J. Kirz, German Aerospace Center (DLR), Aerodynamics and Flow Technology, Lilienthalplatz 7, 38108 Braunschweig, Germany

## Abstract

On a swept vertical tailplane with infinite span tangential blowing over the shoulder of a deflected rudder is applied. For large rudder deflection angles the flow on the rudder is separated without blowing. A numerical study is conducted with the aim to increase the side force coefficient. This could be required for example for a take-off condition with a one-sided engine failure necessitating the compensation of a large yawing moment. If this criterion is critical for the sizing of the vertical tailplane, active flow control like tangential blowing could help to reduce the size of the vertical tailplane and save weight and fuel. With a continuous slot it is demonstrated that the separation on the rudder can be reduced or avoided. It is shown that by using discrete slots this can be achieved with a smaller momentum coefficient. To analyze the effects of the discrete slots and their jets on each other and their effectivity with regard to the gain in side force coefficient a parameter study is conducted. The number of slots as well as the width of the slots in spanwise direction is varied and the impact of jet velocity changes is also studied. Comparing the results for a constant increase in side force and constant slot width the configuration with the smaller number of slots but a higher jet velocity proved to be the most effective one.

## 1. INTRODUCTION

Active flow control is investigated for a vertical tailplane (VTP) geometry as one of the promising applications of this technology. The vertical tailplane of a transport aircraft is needed for stability and control of the aircraft about the yaw axis. One case determining the size of the VTP is the failure of the critical engine. In the one-engine inoperative (OEI) condition, the resulting asymmetric thrust condition creates a moment around the yaw axis. This must be counteracted by the VTP. Here take-off is a critical flight segment where the flight speed is relatively low and thus also the aerodynamic forces produced by the VTP but the thrust of the engines is high. On the other hand, in cruise flight at high aircraft velocity, the VTP is larger than necessary to satisfy cruise stability requirements for modern transport aircraft with electronic flight control systems. The conclusion is that the VTP size is determined by a rarely occurring failure case. In this critical OEI case the rudder is highly deflected to achieve maximum side force but this also leads to partial separation on the rudder. If the size of the VTP could be reduced by applying some means to increase the side force, drag and weight could be lowered which in turn would lead to a reduction in fuel burn. One possibility is the use of active flow control (AFC). With this the side force coefficient produced by the VTP can be increased without increasing its size by delaying flow separation to higher sideslip and/or rudder deflection angles.

In contrast to passive flow control using for example vortex generators, active flow control has the possibility to be turned on just when needed. On the other hand some source of energy is needed for the AFC system which is not the case for a passive system. For this investigation,

pressurized air is used as the energy source to drive fluidic actuators. These are already used in a wide range of active flow control applications. Among different kinds of blowing techniques tangential blowing over the rudder is selected. The jet exit is located at the end of the fin.

Tangential blowing has already been investigated experimentally and numerically in several studies but mainly for the use on wings [1, 2]. In contrast to the wing, the VTP has a small aspect ratio and a large sweep angle changing its flow characteristics. Thus the results obtained for the wing might not be directly transferable. Concerning AFC application to the VTP, some recent studies were done at NASA and Boeing with a mainly experimental approach [3-7]. However, for these studies different kinds of actuators were used, namely synthetic jets and sweeping jets, what might lead to a different interaction with the flow field. Some numerical investigations were done using the code Overflow. Substantial computational resources were applied to demonstrate the ability to simulate sweeping jets at a 3D vertical tail [8]. In the study presented here a different flow solver as well as different kind of actuator will be used. In addition, no study was found in which the underlying mechanism driving the variable effectivity of different slot configurations along the VTP span with tangential blowing was investigated.

Previous numerical work preceding the studies shown here focused on the sensitivities of different active flow control parameters using a 2D VTP airfoil [9]. The current study is now extended to 3D. This allows examining effects in spanwise direction for which a promising slot distribution along the span shall be found. Therefore, starting from a continuous slot, the variation of the width of discrete slots and with this the size of the gap between

them as well as the variation of the number of slots is the focus of the current work. In addition the velocity of the constant blowing jet is varied. The effects of blowing and the evolving vortex systems are studied as well as their impact on the side force coefficient. Since a whole 3D VTP would mean a large mesh resulting in excessive calculation time, a 2.5D geometry is used. It has an infinite span and a constant chord length but incorporates the sweep angle of the VTP. This setup allows for the investigation of a large number of configurations.

## 2. GEOMETRY SETUP

As usual the airfoil geometry for the VTP is a symmetrical one. Selected is the NACA 63A010 which is a transonic airfoil suited for a conventional transport aircraft. The hinge-line, separating the non-moving part fin and the deflectable rudder, is situated at 67% chord length. Since this is a 2.5D approach, the chord length is kept constant over the span. The sweep angle is similar to that of a VTP leading edge and at about 44°. The rudder deflection angle of about 23° in the direction of the incoming flow is selected due to the occurrence of notable flow separation for these conditions. The side slip angle is zero for all investigations. The geometry is scaled by about 1:11 to correspond to a wind tunnel scale and to make the results more easily comparable with other studies.

In the airfoil geometry a slot is integrated at the end of the fin as shown in FIG. 1 to allow for tangential blowing. The slot height is 0.0006 of the chord length leading to a relatively thin slot. This height was also used for the preceding 2D investigations [9]. A part of the slot is modelled for numerical reasons [10]. The slot length corresponds to 20 times its height and is chosen so that a developed pipe flow is established at the outlet. A small step is located aft of the slot towards the rudder shoulder, which would be expected for a realistic 3D design as well, if only due to material thickness.

FIG. 1: Detail of the blowing slot geometry

Starting from a geometry using a continuous slot, this is replaced by several discrete slots in spanwise direction. Their number, width and the gap size between them are varied. One example is shown in FIG. 2. The span is kept constant for the investigation and the number or width of the actuators is selected to fit this span. Just a limited spanwise section is calculated. The left and right boundaries of this section are set as periodic boundary, resulting in a simulation of an infinite swept wing-type geometry.

FIG. 2: 2.5D VTP section with detail view of four slots

## 3. MESH GENERATION

For the mesh generation the commercial software Centaur by CentaurSoft is used [11]. It creates hybrid meshes. The surface mesh consists of triangles or quadrilaterals. The near surface mesh is filled with prisms or hexahedrons and the remainder of the flow field with tetrahedrons. The slots itself and also the rudder are meshed with quadrilaterals or hexahedrons where ever possible. In addition, the flow field behind and above the rudder is discretized with hexahedrons which are less dissipative and should lead to a better preservation of the flow quantities. In this area separated flow for the cases without or insufficient blowing or vortices due to the blowing jets is expected. An overview of the mesh in the vicinity of the vertical tailplane section is given in FIG. 3.

Immediately behind the slot the structured hexahedron mesh layers are reduced by the mesh generator in the corner of the step before growing again as shown in FIG. 4 and with a more detailed view in FIG. 5. Here some tetrahedrons must be used instead of the hexahedrons. This area is kept as small as possible by a rapid growth of the number of layers on the rudder shoulder.

## 4. FLOW SIMULATION

The flow computations were carried out with the flow solver TAU, release 2015.1.0, developed by DLR (Deutsches Zentrum für Luft- und Raumfahrt, German Aerospace Center) [12].

The TAU software solves the Reynolds-averaged Navier-Stokes (RANS) equations or alternatively the Euler equations using numerical methods in two or three dimensions on unstructured and hybrid grids. A finite volume method is applied for the spatial discretization.

The temporal discretization is achieved by a semi-implicit Backward-Euler scheme with the linear LUSGS (Lower-Upper Symmetric Gauss-Seidel) solver. The inviscid flux discretization type for the first stage of iterations is a first order upwind scheme, thereafter switching to the central scheme introduced by Jameson.

A matrix dissipation scheme is employed for low numerical dissipation. For convergence acceleration a 3w multigrid scheme is used. The Reynolds number is  $Re = 2.24 \times 10^6$  based on the VTP airfoil chord length at a Mach number of  $Ma = 0.2$ .

The viscous, fully turbulent RANS calculations were performed using the turbulence model of Spalart and Allmaras [13] enhanced with a vortical and rotational flow correction (SARC) based on the approach of Spalart-Shur [14]. For circulation control airfoils it was shown that this turbulence model leads to good results for flows with high streamline curvature [15].

For the calculations with blowing activated, an actuation boundary condition is specified at the upstream wall of the slot to inject the jet flow into the flow domain. For this boundary condition a specification of jet velocity and density is necessary, with the latter assumed to be identical to the value of the flow in the farfield. Steady RANS calculations are performed with a constant blowing jet.

When comparing the results of the flow simulations, the dimensionless momentum coefficient  $C_\mu$  is used. It is defined as:

$$(1) \quad C_\mu = \frac{v_j^2 * \rho_j * A_j}{0.5 * \rho_\infty * v_\infty^2 * A_{ref}}$$

where  $\dot{m}_j = v_j * \rho_j * A_j$  is the mass flow rate of the jet through the actuator slot with the jet velocity  $v_j$ , the jet density  $\rho_j$  and the area of the slot exit  $A_j$ . The variables  $\rho_\infty$  and  $v_\infty$  are the density and velocity of the onset flow in the farfield,  $A_{ref}$  is the reference area of the model used.

The convergence of the calculations is dependent on the momentum coefficient used and the ability to reduce the areas of separated flow. Without blowing the rudder is fully separated leading to an oscillating convergence. The calculations with the main jet velocity for this study ( $v_j = 207\text{m/s}$ ) as well as the calculations with differing jet velocities but  $C_\mu \geq 0.5$  showed a standard deviation of the side force coefficient below  $10^{-4}$  and a standard deviation of the drag coefficient below  $10^{-5}$  for an averaging over the last 3000 iterations. The convergence for both decreased and increased jet velocities was slightly worse in the case of low momentum coefficients. The worst case showed a standard deviation of the side force coefficient of about 1.5% of its mean value.

## 5. RESULTS

In this chapter results will be presented initially for the case without blowing and for the continuous slot configuration. In a next step discrete slots will be introduced and their effect on the side force coefficients will be shown and discussed.

### 5.1. Continuous Slot

The largest slot width in spanwise direction can be obtained with a continuous slot. Since the slot height is fixed in this investigation, this leads to the largest slot exit area and thus to the largest mass flow rate for a given jet velocity. Therefore the side force coefficients obtained here are used as a reference to judge the effectivity of the later performed slot variations.

To compare the effect of the activation of the AFC, the results for the calculation without blowing are used as a reference. Without flow control the flow on the rudder is mostly separated for the rudder deflection angle selected. This is visualized in FIG. 6 a) where the velocity profiles just behind the rudder shoulder show an inflection point and reversed flow.

In a next step the momentum coefficient is increased gradually. At a momentum coefficient of  $C_\mu = 1\%$  the flow on the rudder is fully attached. In FIG. 6 b) the velocity profiles for this  $C_\mu$  near the rudder shoulder are presented. The effect of the jet blowing tangentially over the surface can be visualized. The jet velocity is higher than the surrounding local flow velocity. This leads to an increase of the flow velocity near the surface and to the bump seen in the velocity profile.

With increasing jet velocity or increasing  $C_\mu$  the side force coefficient  $C_Y$  is increased and the drag coefficient  $C_D$  decreased as depicted in FIG. 7. The increment in  $C_Y$  and  $C_D$  depicted is the difference to the value obtained for the calculation without blowing ( $C_\mu = 0$ ). The force coefficients are obtained by integration of the surface pressure and friction drag excluding the jet boundary plane. With increasing  $C_\mu$  the energy introduced close to the rudder surface by the jet increases. Due to this the flow can better sustain the adverse pressure gradient further downstream on the rudder and the area of separated flow is reduced. Beyond  $C_\mu = 1\%$ , where the flow is fully attached up to the rudder trailing edge, the  $C_Y$  increases further but the efficiency of the blowing reduces. In this region for the same amount of additional  $C_\mu$  a smaller increase in  $C_Y$  is obtained. The decrease in  $C_D$  is due to the reduction of the separation on the rudder leading to a decrease in pressure drag.

FIG. 6: Velocity vectors near the slot and on the rudder shoulder (length of vectors in a) twice that of b)

FIG. 7: Side force and drag coefficient increment over a variation of the momentum coefficient for the continuous slot

In FIG. 8 the surface pressure coefficient is shown for a selected momentum coefficient of  $C_{\mu}=0.8\%$ . This  $C_{\mu}$  is smaller than needed for the flow to stay attached up to the trailing edge. The two suction peaks at the fin leading edge and at the rudder shoulder are clearly visible which increase the more the flow on the rudder is attached. The stream traces on the fin visualize the high sweep angle of the incoming flow. On the rudder the flow does not follow this direction but is turned in the direction of the blowing jet which is perpendicular to the hinge-line. This effect increases as the momentum coefficient is increased. Since the  $C_{\mu}$  is not large enough, separated flow - with the stream traces oriented in spanwise direction - is still visible towards the trailing edge.

FIG. 8: Surface pressure coefficient  $C_p$  and stream traces for the continuous slot,  $C_{\mu}=0.8\%$

## 5.2. Discrete Slot Variations

Having the continuous slot results as a reference, the area of the slot and its length in spanwise direction is now reduced. For the comparison of the results, three different jet velocities are investigated. These are selected based on the results for the continuous slot and correspond to momentum coefficients obtained there with 1%, 1.5% and 2%. The respective jet velocities  $v_j$  are: 169m/s, 207m/s and 239m/s. Keeping  $C_{\mu}$  constant may not lead to a meaningful comparison for this investigation since this would lead to a very small jet velocity for slots with large width compared to small slots where the jet velocity would be very high and could also exceed the supersonic speed. Apart from the jet velocity the number of the slots  $N$  and the slot width  $w$  are varied. Since the span is kept

constant, the length of the gap between the slots results from the variation of the two former parameters.

### 5.2.1. Flow Effects with Discrete Slots

Replacing the continuous slot with several discrete slots changes the flow topology on the rudder. When blowing from the discrete slots longitudinal vortices are created downstream of the rudder shoulder. These vortices are counter-rotating and are depicted for one selected case in FIG. 9. Field slices on the rudder are colored for the visualization of the vortices with  $\omega_x$ , the rotation direction in x-direction. From the observer point of view the blue vortices with negative  $\omega_x$ , which are on the right of the vortex pair, are rotating clockwise and the red ones left to them rotate counter-clockwise.

FIG. 9: Stream traces and field slices showing the vortices ( $N=4$ ,  $w=9.6\text{mm}$ ,  $v_j=239\text{m/s}$ ,  $C_{\mu}=0.5\%$ )

Two effects make it possible for the vortices to develop. The first one is that the slot has a discrete length creating a jet which has edges left and right. The second effect is that the actuator blowing direction has an angle relative to the incoming flow.

The main flow direction is inclined by about  $44^\circ$  to the blowing direction of the jets as visualized in FIG. 10 a) when looking from the top at the vertical tailplane section in the region of the slot exit and rudder shoulder. The flow coming from the fin approaches the faster jet flow from the slot and bypasses it by going for this higher momentum coefficient above it. The shearing between the two flow layers induces the rotation leading to the blue vortex in FIG. 9 which is the right one of the vortex pair. The upwind produced on its' one side induces the counter-rotating red vortex. This leads to an upwind region in the middle of a vortex pair which takes energy and fast moving fluid away from the surface and is locally disadvantageous. Between two vortex pairs created at two different jets the rotation direction is downwards to the surface which has an advantageous effect stabilizing the boundary layer. This helps to keep the flow on the rudder attached also in the regions between the jets. The generation of the vortices and their efficiency is dependent on the slot width and number of slots as well as on the jet velocity. Results for this parameter variation are presented in the next section.

FIG. 10: View on the slot and part of the rudder shoulder; the stream traces shown are the same in both figures

### 5.2.2. Effects with Constant Jet Velocity

In this section the influence on the side force coefficient is discussed for a study of a constant jet velocity while varying the number of slots and the slot width. From this it can be determined which slot configuration is most effective at a given jet velocity.

In FIG. 11 the increment of the side force coefficient  $\Delta C_Y$  related to the value without blowing for the continuous slot versus the momentum coefficient  $C_{\mu}$  is presented for a fixed jet velocity of  $v_j=207\text{m/s}$ . For one data row the number of slots is constant while the slot width is increased with increasing  $C_{\mu}$ . For data points with the same  $C_{\mu}$  also the accumulated slot length is the same. The dotted line shows the results of the continuous slot while only the data point at  $C_{\mu}=1.5\%$  on this curve is the one for the jet velocity considered. Since the slot area is larger for the continuous slot than for the discrete slots, the jet velocity has to be smaller for the same  $C_{\mu}$ .

FIG. 11: Variation of  $C_Y$  versus  $C_{\mu}$  at  $v_j=207\text{m/s}$

The figure reveals that for the same  $C_{\mu}$  all results with discrete slots lead to a higher  $C_Y$  than the continuous slot. Thereby the side force coefficient is increasing with increasing  $C_{\mu}$ . In general three different regions with different effects can be observed and are discussed in the following.

#### 5.2.2.1. Region $C_{\mu}<0.35\%$

The end of this region is marked in FIG. 11 with the vertical dashed line at  $C_{\mu}=0.35\%$ . Here the momentum coefficient is rather small. In this region the highest side force coefficient is obtained by a single slot and reduces with an increased number of slots. To give a more detailed discussion of the flow effects, the results at  $C_{\mu}=0.19\%$  - or

to be exact at  $C_{\mu}=0.1875\%$  - are selected for one, two and four slots which are circled by a line in FIG. 11. Since the given jet velocity is constant here, this factor of 1/8 in the momentum coefficient compared to the continuous slot result at  $C_{\mu}=1.5\%$  is due to the reduction in the slot area by this factor according to Equ.(1). This means that the mass flow rate is also reduced by this factor, while especially for the one-slot configuration the resulting side force increment through blowing is much larger than 1/8.

The reason why the one slot configuration leads to the highest increase of  $C_Y$  in this region of small momentum coefficients can be seen in FIG. 12. For the configuration with one slot with a large width, compare FIG. 12 a), the created vortices over the rudder have a much larger diameter than for the configuration with four smaller slots in FIG. 12 b). The vortices introduce energy from the outer flow in the region close to the surface. This enables the flow to stay attached to the surface on the rudder in this region. With the two or four slots the vortices are smaller. Therefore the amount of energy they can bring to the surface is smaller and the flow close to the rudder separates earlier. In addition, the vortices of the one slot configuration are closer to the surface for a larger length of the rudder chord and thus have an increased influence while the ones for the four slots move away from the surface quite quickly.

For this small  $C_{\mu}$  where the jet separates quite quickly from the surface, the induced vortex created by the incoming flow with an angle to the jet passes the jet vortex below it.

FIG. 12: Side view of the rudder with field stream traces ( $v_j=207\text{m/s}$ ,  $C_{\mu}=0.19\%$ )

In FIG. 13, FIG. 14 and FIG. 15 further visualization of the flow for the three slot configurations is shown. In part a) surface streamlines are depicted as well as the negative skin friction coefficient  $C_{fx}$  in blue or darker color which gives an indication of reversed and separated flow. The top view of twice the vertical tailplane section is shown here leading to a doubling of the number of slots in this figure. In part b) field stream traces are depicted colored with total pressure with red being a high and blue a low total pressure. The levels are equal to those in the legend in FIG. 12. The field slices are colored in the vorticity about the x-axis  $\omega_x$ . Here just the blowing direction of the jet is in x-direction and the vortices especially for this low momentum coefficient are more deflected in the direction of the outer flow. Nevertheless, this gives a good impression of the flow and the vortices over the rudder.

FIG. 13:  $N=1$ ,  $w=19.1\text{mm}$ ,  $v_j=207\text{m/s}$ ,  $C_{\mu}=0.19\%$

FIG. 14:  $N=2$ ,  $w=9.6\text{mm}$ ,  $v_j=207\text{m/s}$ ,  $C_{\mu}=0.19\%$

FIG. 15:  $N=4$ ,  $w=4.8\text{mm}$ ,  $v_j=207\text{m/s}$ ,  $C_{\mu}=0.19\%$

For the one large slot in FIG. 13 a large vortex pair is created which leads to an increased area of positive  $C_{fx}$  that reaches also up to the trailing edge. However, due to the large gap between the slots a large area of the rudder is not affected by the vortices leading to separated flow in this region. In the case of the two or four smaller slots the area of positive  $C_{fx}$  on the rudder is reduced. The vortices are less strong and further away from the surface leading to a reduced benefit of the mixing of the outer flow with the boundary layer. This leads in summary to a smaller side force coefficient than for the larger single slot. For this region of small  $C_{\mu}$  it can be concluded that a smaller number of slots with greater lengths are beneficial compared to more but smaller slots.

### 5.2.2.2. Region $0.35\% < C_{\mu} < 0.9\%$

Due to the increased momentum coefficient or mass flow rate resulting from a larger slot length or an increased number of slots, higher values for the side force coefficient are obtained than seen for the smaller  $C_{\mu}$ . In this range of medium  $C_{\mu}$  the efficiency of the one slot configuration

degrades or the efficiency of those with several slots increases. The results for the configurations with one to five slots are quite similar in this region of  $C_{\mu}$ . However, with a large number of slots of eight or ten on the selected span a significant decrease in the gained  $C_Y$  can be observed.

A second circle in FIG. 11 marks the results for  $C_{\mu}=0.38\%$ . Compared to the circled results discussed before at  $C_{\mu}=0.19\%$  the area of the slots is doubled here. In addition, configurations with more slots are added where the slots are closer together, i.e. the gaps are reduced.

For this  $C_{\mu}=0.38\%$  the flow on the rudder is still not attached up to the trailing edge. FIG. 16 shows surface and field results for the configuration with one slot and FIG. 17 those with four slots which lead to the greatest increase in  $C_Y$ . FIG. 18 shows results for the configuration with eight slots which gives the smallest  $C_Y$  for this  $C_{\mu}$ .

FIG. 16:  $N=1$ ,  $w=38.2\text{mm}$ ,  $v_j=207\text{m/s}$ ,  $C_{\mu}=0.38\%$

FIG. 17:  $N=4$ ,  $w=9.6\text{mm}$ ,  $v_j=207\text{m/s}$ ,  $C_{\mu}=0.38\%$

FIG. 18:  $N=8$ ,  $w=4.8\text{mm}$ ,  $v_j=207\text{m/s}$ ,  $C_{\mu}=0.38\%$

Two opposing effects can be observed here. For configurations with a large slot width and therefore also large gaps between the slots, the vortex system does not cover the whole span. Due to this, areas with separated flow exist between them, reducing the side force coefficient. On the other hand a too dense slot spacing hinders the development of sufficiently large vortex structures as can be observed in FIG. 18 for eight slots. Here the second vortex of each pair is relatively small and weak in its magnitude of  $\omega_x$ .

Therefore the intermediate arrangement with the four slots leads to the highest increase in the side force coefficient. The distance between the vortex pairs is such that the flow between them is attached. A small area of reversed flow is still visible near the trailing edge in FIG. 17 a). Here an increase in the jet velocity to 239m/s would add enough energy to the boundary layer to enable the flow to stay attached to the rudder up to the trailing edge.

Some small regions of reversed flow are visible between the blowing jets near the rudder shoulder where the separation would start without blowing. Since the vortices are not yet developed in this area, mainly the region along the span where the slots are positioned show attached flow. The jets widen towards the trailing edge and are then in combination with the fully developed vortex system able to cover the whole span further downstream on the rudder.

Increasing the accumulated slot area over the given span further by doubling it again, leads to a slot area which is half that of the continuous slot. This would refer to the points circled in FIG. 11 at a  $C_{\mu}=0.75\%$ . The observations made before are applicable here as well. Due to an increased mass flow rate by larger or more slots the flow on the rudder is attached up to the rudder trailing edge for most configurations. The differences in the gained  $C_Y$  for the different configurations reduce compared to the smaller momentum coefficients.

### 5.2.2.3. Region $C_{\mu} > 0.9\%$

For large momentum coefficients the differences in the values of the obtained side force coefficient increments decrease for the different slot configurations. The values are approaching those of the continuous slot case which is marked at  $C_{\mu}=1.5\%$  in FIG. 11. For this the maximum increase in  $C_Y$  for this jet velocity can be achieved but it also requires the largest mass flow rate making it less efficient.

### 5.2.2.4. Variation of the Jet Velocity

Increasing the jet velocity from 207m/s to 239m/s or decreasing it to 169m/s leads in principle to a shift of the curves shown in FIG. 11. For the higher jet velocity the gain in  $C_Y$  is slightly increased in the same range of  $C_{\mu}$  and since higher  $C_{\mu}$  values can be obtained also the achievable side force coefficient is increased. The opposite is true for the lower jet velocity. The respective diagrams are shown in FIG. 19 and FIG. 20.

In addition it can be observed that for the different slot configurations at the same  $C_{\mu}$  the obtained  $C_Y$  is more similar for the large jet velocity. For the smaller jet velocity

the variation in the side force coefficient is much larger for the same momentum coefficient and the reduced efficiency of more but smaller slots even more noticeable.

FIG. 19: Variation of  $C_Y$  versus  $C_{\mu}$  at  $v_j=169\text{m/s}$

FIG. 20: Variation of  $C_Y$  versus  $C_{\mu}$  at  $v_j=239\text{m/s}$

### 5.2.3. Effects with Constant Slot Width

Until now the jet velocity was kept constant. In this section the results are discussed under the viewpoint of a constant slot width. Selected is a slot width of  $w=9.6\text{mm}$ . With the slot width being fixed, now the number of slots  $N$  and with this also the gap between the slots  $g$  can be varied to judge how many slots are necessary to keep the flow on the rudder attached. The results are shown in FIG. 21. In addition, the effect of the jet velocity is monitored. Each data row consists of results for the three different jet velocities of 169m/s, 207m/s and 239m/s. The smallest jet velocity leads to the lowest increase in  $C_Y$  for each row of data.

FIG. 21: Variation of  $C_Y$  versus  $C_{\mu}$  at a constant slot width  $w=9.6\text{mm}$  and varying gap size  $g$

The discussion of the results is possible for a constant  $C_{\mu}$  and for a constant  $\Delta C_Y$ . Both will be done in the following.

### 5.2.3.1. Constant Momentum Coefficient

At a  $C_{\mu}=0.38\%$  three results are circled and chosen for the subsequent discussion. For these the rudder is not attached completely yet. The areas with negative skin friction coefficient  $C_{fx}$  are marked in FIG. 22 for these three results. In this figure twice the span is shown.

The result with  $N=3$  has the lowest number of slots but the highest jet velocity and also the largest increase in  $\Delta C_Y$ . Here the flow is practically fully attached up to the trailing edge but larger areas of separated flow exist between the slots. The result with the largest number of slots  $N=6$  has the smallest jet velocity. The areas of reversed flow between the slots is very small but since the jet velocity is the lowest, not enough energy is added to the boundary layer making it more difficult to overcome the adverse pressure gradient leading finally to the separation of the flow from the rudder and the reduced gain in  $\Delta C_Y$ . The results for the configuration  $N=4$  slots and the medium slot velocity has both effects of separated regions between the jets close to the rudder shoulder and some separation near the trailing edge. However, these are less distinct than for the two other configurations and lead in the end to a  $\Delta C_Y$  close to the one with  $N=3$ .

In summary it can be stated that for the same  $C_{\mu}$  a lower number of slots with a higher jet velocity gives the largest gain in the side force coefficient.

a)  $N=3$ ,  $v_j=239\text{m/s}$       b)  $N=4$ ,  $v_j=207\text{m/s}$       c)  $N=6$ ,  $v_j=169\text{m/s}$

FIG. 22: Top view onto the vertical tailplane section showing  $C_{fx}<0$  and surface stream traces ( $w=9.6\text{mm}$ ,  $C_{\mu}=0.38\%$ )

### 5.2.3.2. Constant $\Delta C_Y$

In a second step those results are discussed which lead to a similar increase in the side force coefficient. Now a horizontally oriented selection is circled by a line in FIG. 21 for a  $\Delta C_Y$  of about 0.42. All configurations show attached flow up to the trailing edge but the size of the areas of separated flow between the jets close to the rudder shoulder differs. Although the same gain in  $C_Y$  is obtained, the required momentum coefficient is quite different for each case.

The most effective configuration is the one with  $N=4$  and the highest jet velocity requiring a  $C_{\mu}=0.5\%$ . Compared to the continuous slot this means a large reduction of the momentum coefficient by 50%. When considering the mass flow rate this would correspond to a reduction of 65% compared to the continuous slot.

For the configuration with four slots the spacing of the slots seems optimal to cover the span with the vortex system as shown in FIG. 23 a). Increasing the number of slots reduces the distance between them too much so that the vortex pairs cannot fully develop. For  $N=8$  this is shown in FIG. 23 b). For the continuous slot no vortices can be found at all.

a)  $N=4$ ,  $v_j=239\text{m/s}$ ,  $C_{\mu}=0.5$       b)  $N=8$ ,  $v_j=207\text{m/s}$ ,  $C_{\mu}=0.75$

With an increasing number of slots the accumulated slot area increases due to the constant width. On the other hand the jet velocity for the configurations with  $N=6$  and  $N=8$  slots is smaller than for the configuration with four slots and the smallest for the continuous slot. However, the increase in the slot area outweighs the velocity decrease, leading to an increase in  $C_{\mu}$  for the configurations with more slots.

In summary it can be found that the configuration with the highest jet velocity and the smaller number of slots leads to the most effective configuration.

## 6. CONCLUSION

For a 2.5D vertical tailplane tangential blowing over the shoulder of a deflected rudder is investigated in a numerical study. Starting with a configuration with a continuous slot extending over the whole span this is replaced by configurations with discrete slots. The number of slots, their width as well as the jet velocity is varied. The aim is the increase of the side force coefficient.

Steady calculations are performed using the Reynolds-averaged Navier-Stokes equations with the flow solver TAU.

Without the tangential blowing the flow on the rudder of the vertical tailplane is separated. With blowing activated and a sufficient jet velocity the flow could be held attached for the continuous slot. Using discrete slots additional effects could be observed, which make these configurations more efficient.

It could be shown that for the discrete slots a pair of counter-rotating vortices is created if they have sufficient space between them. In addition to the energy fed to the boundary layer by the jet itself this leads to an increased mixing of the outer and near surface flow increasing the energy of the boundary layer as well. Due to this the separated flow could be reduced or even avoided.

For small momentum coefficients  $C_{\mu}<0.3\%$  a defined increment in  $C_{\mu}$  leads to a relatively large increase in the

side force coefficient  $C_Y$ . However, the flow on the rudder is not fully attached so the gain in  $C_Y$  is limited. By increasing the momentum coefficient the separation on the rudder can be reduced but the increase in  $C_Y$  per  $\Delta C_{\mu}$  decreases.

For  $C_{\mu} < 0.3\%$  the configuration with one slot leads to the largest increase in  $C_Y$  because the created vortex pair is the largest. With increased  $C_{\mu}$  for a constant jet velocity the size of the slot gets larger than necessary to create a sufficiently large vortex pair. Since the gap between the slots is quite large as well, areas of separation can be found there. On the other hand having a too small gap between the slots is also not beneficial as the development of the vortex system is suppressed. An optimal configuration was found for a number of slots of four on the defined span with a slot width of 9.6mm and a gap between them of 28.7mm. Using a  $C_{\mu} = 0.5\%$  an attached flow could be achieved on the rudder. This is half the  $C_{\mu}$  required for the continuous slot.

In general it can be stated that for a constant slot width the configuration which combines a small number of slots with a large jet velocity is most effective for a similar increase in the side force coefficient.

One interesting next step would now be the transfer of these results to a 3D vertical tailplane where additional 3D effects will have an influence.
